## アトリCHE．

FRAGMENTS OF THE COARSER ANATOMY OF DIURNAL LEPIDOPTERA．<br>BY SAMUEL H．S（ULDER，CAMBHIDGE，MASS．<br>6．THE LARVA OF HAMADRYAS IO．OF ELROPE．<br>（Contimued from p．275．）

Nerens system．The cephalic lobes are rertically subprriform，the apex downward．The third and fourth borly－ ganglia are almost as near each other as the third is to the origin of the nerves which spring from the cord in advance of the third ganglion，and the two rib－ hons which connect them are a very little parted．

Glundular system．Each of the silk－ ressels is formed of an initial thread， 0.05 mm ．in diameter，which is abont one－seventh of the entire length，and a cylindrical tube，of four times the size of the thread ；this terminates abruptly in a pointed tip，from which a delicate －thread trails，and this thread is attached to the under part of the sides of the front of the intestine ；the whole has a slightly wayy course，running at first near its mate on the under side of the body，as far as the second abdominal segment； then，turning abruptly and a little upward to above the middle of the body，it con－ tinues its former direction．

Mule generative orguns．The testes are situated in the middle of the dorsum of the fifth abdominal segment，as in Dunuis；they have only a slight rosy tinge across the middle are 1.5 mm ． long by half that width，and are subreni－ form in shape．

Femule generative nigans．The ovaries in the female are situated in the same place as the testes in the male， and consist of a pair of long ohorate sacs， 2 mm ．long and about 0.5 mm ．broad， bluntly rounded at each end，vertically disposed，approximated，but with the lower end curved outward；they are white，and each consists of a bundle of similar tubes．

Rutiments of wings．Each of the wing－pads in the full－grown larva is formed of a pellucid，compressed， rounded，nearly hemispherical sac，fully 2 mm ．long and a little longer than broad．abundantly permeated by white branching threads which do not seem to extend into the very base of the wing－ parls；they are situated，base downward and convexity outward，just above and scarcely in advance of the base of the tracheae of the third thoracic segment， and at a corresponding position on the second segment ：the membrane is slightly opaque and granulated：the permeating ressels are composed of bunches of numerons，minute and perfectly equal threads，varying in length and in num－ ber；they appear to be hollow and are 0.0025 mm ．in diameter．A figure will be found in my work on Butterflies， already cited． 1 ． $9 \overline{3}$.

## 7. THE PUPA OF HAMADRYAN IO. OF ELROPE.

Muscular system. Iu general the muscles of the abdomen seem to be situated much as in the larva, but are more compact and almost or altogether longitudinal, the oblique muscles disappearing. Those of the under surface of the abdomen consist. on each side of the body. of a ribbon, one millimetre broad, composed of two contiguons strips, the onter slightly the broader, rumning next the integument through the entire length of the abdomen, the inner edge at one millimetre's distance from the nervons cord.

Digestive system. The oesophagns is a slender, thread-like tube, less than 0.1 mm . in diameter ; as it euters the abdomen it is at once directed upward and suddenly expands into a small bulbous muscular crop, the upper part of which opens into the reservoir, a subfusiform blind sac, broadly rounded at tip, 1.5 mm . in breadth and 5 mm . long, reaching the extremity of the fourth abdominal segment: immediately on the apical contraction of the crop, the stomach arises; this is at once many times broader than the crop, and remains nearly of this size. to the tip of the fourth abdominal segment (or where the reservoir ends) ; from this point on it is only half its former diameter and extends as a straight tube to the middle of the fifth abclominal segment. On each side, at the base, the stomach bears some rounded lobes, nearly as large as the crop, and besides these, arranged in a row down each side of the merlian line, it is profusely covered with small pea-like
pockets. The intestine is tortuons, of considerable length, $0.15-0.18 \mathrm{~mm}$. in diameter, and ends in the colon, a blad-der-like sac, pyriform in shape and about 0.8 mm . long, containing a whitish substance: this opens into the rectum, a broad and straight tube, 1.5 mm . long and 0.2 .5 mm . broad.

The salivary glands are composed of threads about 35 mm . long, and of a uniform size thronghout; they first run straight beside the slender oesophagus. until near the middle of the mesothorax. when they become very strongly crinkled, forming by their convolutions a fusiform mass, 3.25 mm . long and 0.5 mm . broad. continning in the same course to the middle of the metathorax.

The malpighian ressels arise at the extremity of the smaller part of the stomach, without the intervention of any basal sac, three branches arising together at the a very short distance from the base of their common stem and parting from it at right angles.

Respiratory system. The tracheae seem to be much as in the larva, only greatly reduced in size, very delicate, not at all opaque, and not divided into two sorts ; the lateral longitudinal canal of the abdomen appears to be larger than any of the other vessels.

Circulutory system. The dorsal vessel is a slender, equal canal, terminating abruptly behind at the tip of the fourth abdominal segment. lying next the integment of the finture imago and about 0.15 mm . in diameter in the abdomen; as it enters the thorax from behind it
plunges downward to just above the oesophagus in advance of the crop, then passes rapidly upward again to the integument, which it follows to the middle of the mesothorax, dminished to half its former size, so as to appear a mere thread, and then, casting free again, passes forward as in the larva, reaching the oesophagns again in the prothorax, where it appears to be attached to something, which was not made out; beyond this point it was not tracerl.

Nervous system. Between the cephalic and thoracic ganglia the nervous cord is moderately broad, flattened and double ; the thoracic ganglion is sitnated in the fiont part of the mesothorax ; it is oval and evidently composed of two unequal, anterior and posterior, elements. for slightly in front of the middle it is pienced by a vertical passage of considerable size, and the portion in front of it has a slight, independent tumidity; the whole is a little more than 1.5 mm . long and less than half as broad, tapering posteriorly; from near the middle it emits lateral nerves. which pass toward the wings, and just before the hinder end a rather prominent nerve, which rmus backward, parallel to the main cord and nearly as large as it, half way to the abdomen, evidently feeding the legs; besides these there is another similar pair. also running backward but divaricating a little. which originates from the witlest part of the posterior portion. The cord itself is rather slender. and runs without enlarging until it reaches the abdomen, when it appears gradually to thicken and form a pseudnganglion of an elongate. fusiform shape, nearly 1.5 mm . long and terminating just before
the first abdominal ganglion ; this appearance, however, is produced by the fact that thronghout the abdomen the cord is overlaid by an investment mainly pellucid, but not pellueid enough to allow the true cord to the seen, excepting from beneath ; this investment does not cover the ganglia to an equal extent, but only as a film; so that the abdominal development of the nervous system is an exceedingly delicate cord, expanding at four different points into lenticular, disk-like ganglia of a small size, but many times excceding the cord in diameter, the whole enwrapped in a semi-pellucid investment which makes it appear of nearly uniform diamster, excepting in front of the first true abdominal ganglion, where the investment becomes swollen and less pellneid, resembling a greatly elongated ganglion. The abdominal ganglia are 2.25 mm . apart ; the first, which is scarcely broader than the cord, and noticeable mainly by its whitish color, is situated near the end of the second segment; the second at the heginning of the fourth; the third at the beginning of the fifch, and the last in the middle ot the sixth segment ; the last is larger than the others and emits four delicate posterior nerves; each of the ablominal ganglia is also provided with lateral nerves, similar to, but more delieate than, those of the larva.

In Newport's observations on the changes in the nervous corrl of Aglais urticue,* he shows a more considerable change between forty-eight and fiftyeight hours than perhaps between any others of the stages he has drawn and

[^0]described, which are stecessively (after the pupal state is assmmed) $1,13,18$, $\geq 4,36,48$, and 58 hom's. Aceording to his aceoment the second and third (original) ganglia at this period "approach and coalesce, and the double ganglion thus formed is only separated from the larger thoracie mass, composed of the fourth and fifth ganglia, and part of the sixth. by very short but much enlarged cords." As the figures given ly him do not in themselves show how this amalgamation of the second and third ganglia is effected, I examined the nervons cord of the present species, Hamudryas io, 48. 51 and 55 hours atter pupation, with the following results: The pupa of 48 hour's age differs from that of Agluis riticue only in the separation of the fourth ganglion from the united fifth and sixth : very short and broad ribbons connected them, but they were immistakably separated by half the width of the fourth ganglion; while the thitr and fourth ganglia were separated ly about the diameter of the latter ganglion. At 51 hours the condition was more as
represented by Newport at 48 hours in A. witioro, the fourth, fifth and sixth ganglia being completely amalgamated into a single long ovate mass, while the thirth thongh clearly distinct from the mass behind it, wats separated from it by only less than half its own diameter, very short, stout ribhons uniting the two; it was also of the same size as at ts hours, and the second ganglion, instead of travelling toward the third, as Newport asserts, retained very nearly or quite its own place, but was reduced in size, being gradually aborbed in place by the cord. This absorption was entirely effected at 5.5 hours, as also was the complete amalgamation of the third ganglion with the mass behind it. The second ganglion then is not amalgamater with the third. but disappears in placea point quite in keeping with the lessening importance. but continned integrity, of the prothorax generally.

Mule generative organs. The testes form a globular mass $1 . j \mathrm{~mm}$. in dianeter.
(To be continued on p.307.)

## IYLOCOPA PERFORATING A COROLLA-TUBE.

## BY B: PICKMAN MANN, WASHINGTON, I. (.

Is October 1881 I noticed a Xylocopa perforating the corolla-tube of a salvershaped flower, somewhat resembling that of a Petumia. The bee alighted on the five-lobed spreading top of the flower, which, as the flowers grew, was situated almost perpendicularly to the horizon, and immediately crawled over the edge, between the lobes, so as to reach the outside of the tube, which was somewhat
fluted. Applying its sharp and wedgeshaped maxillae to the groored surface of the tube, it split this open, three or four millimetres from the base, and continued the split to the base, where the nectar was situated. It then sucked ont the nectar quickly, and proceeded to another flower, upon which the operation was repeated.
